

# SUPPLEMENTARY MATERIALS: COMPUTING SOLUTION SPACE PROPERTIES OF COMBINATORIAL OPTIMIZATION PROBLEMS VIA GENERIC TENSOR NETWORKS

JIN-GUO LIU\*, XUN GAO†, MADELYN CAIN‡, MIKHAIL D. LUKIN†, AND SHENG-TAO WANG‡

**SM1. Performance benchmarks.** We run a single thread benchmark on central processing units (CPU) Intel(R) Xeon(R) CPU E5-2686 v4 @ 2.30GHz, and its CUDA version on a GPU Tesla V100-SXM2 16G. The results are summarized in [Figure SM1](#). The graphs in all benchmarks are random three-regular graphs, which have treewidth that is asymptotically smaller than  $|V|/6$  [[SM4](#)]. In this benchmark, we do not include traditional algorithms for finding the MIS sizes such as branching [[SM10](#), [SM9](#)] or dynamic programming [[SM2](#), [SM5](#)]. To the best of our knowledge, these algorithms are not suitable for computing most of the solution space properties mentioned in this paper. The main goal of this section is to show the relative computation time for calculating different solution space properties.

[Figure SM1\(a\)](#) shows the time and space complexity of tensor network contraction for different graph sizes. The contraction order is obtained using the local search algorithm in Ref. [[SM7](#)]. If we assume our contraction-order finding program has found the optimal treewidth, which is very likely to be true, the space complexity is the same as the treewidth of the problem graph. Slicing technique [[SM7](#)] has been used for graphs with space complexity greater than  $2^{27}$  (above the yellow dashed line) to fit the computation into a 16GB memory. One can see that all the computation times in [Figure SM1 \(b\), \(c\), and \(d\)](#) have a strong correlation with the predicted time and space complexity. While in panel (d), the computation time of configuration enumeration and sum-product expression tree generation also strongly correlates with other factors such as the configuration space size. Among these benchmarks, computational tasks with data types real numbers, complex numbers, or tropical numbers (CPU only) can utilize fast basic linear algebra subprograms (BLAS) functions. These tasks usually compute much faster than ones with other element types in the same category. Immutable data types with no reference to other values can be compiled to GPU devices that run much faster than CPUs in all cases when the problem scale is big enough. These data types do not include those defined in [Equation \(5.2: PN\)](#), [Equation \(7.1: SN\)](#), [Equation \(8.1: Tk\)](#) and [Equation \(7.7: EXPR\)](#) or a data type containing them as a part. In [Figure SM1\(c\)](#), one can see the Fourier transformation-based method is the fastest in computing the independence polynomial, but it may suffer from round-off errors ([Section SM3](#)). The finite field ( $\text{GF}(p)$ ) approach is the only method that does not have round-off errors and can be run on a GPU. In [Figure SM1\(d\)](#), one can see the technique to bound the enumeration space in [Appendix C](#) improves the performance for more than one order of magnitude in enumerating the MISs. The bounding technique can also reduce the memory usage significantly, without which the largest computable graph size is only  $\sim 150$  on a device with 32GB main memory.

We show the benchmark of computing the maximal independent set properties on 3-regular graphs in [Figure SM2](#), including a comparison to the Bron-Kerbosch algorithm from Julia package [Graphs](#) [[SM3](#)]. [Figure SM2\(a\)](#) shows the space and time complexities of

Figure SM1: Benchmark results for computing different solution space properties of independent sets of random three-regular graphs with different tensor element types. The time in these plots only includes tensor network contraction, without taking into account the contraction order finding and just-in-time compilation time. Legends are properties, algebra, and devices that we used in the computation; one can find the corresponding computed solution space property in Table 1 in the main text. (a) time and space complexity versus the number of vertices for the benchmarked graphs. (b) The computation time for calculating the MIS size and for counting the number of all independent sets (ISs), the number of MISs, the number of independent sets having size  $\alpha(G)$  and  $\alpha(G) - 1$ , and finding 100 largest set sizes. (c) The computation time for calculating the independence polynomials with different approaches. (d) The computation time for configuration enumeration, including single MIS configuration, the enumeration of all independent set configurations, all MIS configurations, all independent sets, and all independent set configurations having size  $\alpha(G)$  and  $\alpha(G) - 1$ .

43 tensor contraction, which are typically larger than those for the independent set problem. In  
 44 [Figure SM2\(b\)](#), one can see counting maximal independent sets are much more efficient than  
 45 enumerating them, while our generic tensor network approach runs slightly faster than the  
 46 Bron-Kerbosch approach in enumerating all maximal independent sets.

47 **SM2. An example of increased contraction complexity for the standard tensor**  
 48 **network notation.** In the standard Einstein's notation for tensor networks in physics, each  
 49 index appears precisely twice: either both are in input tensors (which will be summed over)  
 50 or one is in an input tensor and another in the output tensor. Hence a tensor network can be  
 51 represented as an open simple graph, where an input tensor is mapped to a vertex, a label  
 52 shared by two input tensors is mapped to an edge and a label that appears in the output  
 53 tensor is mapped to an open edge. A standard tensor network notation is equivalent to the

SM2

Figure SM2: Benchmarks of computing different solution space properties of the maximal independent sets (ISs) problem on random three regular graphs at different sizes. (a) time and space complexity of tensor network contraction. (b) The wall clock time for counting and enumeration of maximal ISs.

generalized tensor network in representation power. A generalized tensor network can be converted to a standard one by adding a  $\delta$  tensors at each hyperedge, where a  $\delta$  tensor of rank  $d$  is defined as

$$(SM2.1) \quad \delta_{i_1, i_2, \dots, i_d} = \begin{cases} 1, & i_1 = i_2 = \dots = i_d, \\ 0, & \text{otherwise.} \end{cases}$$

In the following example, we will show this conversion might increase the contraction complexity of a tensor network. Let us consider the following King's graph.

The generalized tensor network for solving the MIS problem on this graph has the following hypergraph representation, where we use different colors to distinguish different hyperedges.

SM3

Vertex tensors are not shown here because they can be absorbed into an edge tensor and hence do not change the contraction complexity. If we contract this tensor network in the column-wise order, the maximum intermediate tensor has rank  $\sim L$ , which can be seen by counting the number of colors at the cut.

By adding  $\delta$  tensors to hyperedges, we have the standard tensor network represented as the following simple graph.

In this diagram, the additional  $\delta$  tensors can have ranks up to 8. If we still contract this tensor network in a column-wise order, the maximum intermediate tensor has rank  $\sim 3L$ , i.e. the space complexity is  $\approx 2^{3L}$ , which has a larger complexity than using the generalized tensor network notation.

**SM3. The discrete Fourier transform approach to computing the independence polynomial.** In [Appendix D](#) in the main text, we show that the independence polynomial can be obtained by solving the linear equation [Equation \(D.1\)](#) using the finite field algebra. One drawback of using finite field algebra is that its matrix multiplication is less computationally efficient compared with floating-point matrix multiplication. Here, we show an alternative method with standard number types but with controllable round-off errors. Instead of choosing  $x_i$  as random numbers, we can choose them such that they form a geometric sequence in the complex domain  $x_j = r\omega^j$ , where  $r \in \mathbb{R}$  and  $\omega = e^{-2\pi i/(\alpha(G)+1)}$ . The linear equation thus becomes

$$(SM3.1) \quad \begin{pmatrix} 1 & r & r^2 & \dots & r^{\alpha(G)} \\ 1 & r\omega & r^2\omega^2 & \dots & r^{\alpha(G)}\omega^{\alpha(G)} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & r\omega^{\alpha(G)} & r^2\omega^{2\alpha(G)} & \dots & r^{\alpha(G)}\omega^{\alpha(G)^2} \end{pmatrix} \begin{pmatrix} a_0 \\ a_1 \\ \vdots \\ a_{\alpha(G)} \end{pmatrix} = \begin{pmatrix} y_0 \\ y_1 \\ \vdots \\ y_{\alpha(G)} \end{pmatrix}.$$

SM4

84 Let us rearrange the coefficients  $r^j$  to  $a_j$ , the matrix on the left side becomes the discrete  
85 Fourier transform matrix. Thus, we can obtain the coefficients by inverse Fourier transform  
86  $\vec{d}_r = \text{FFT}^{-1}(\omega) \cdot \vec{y}$ , where  $(\vec{d}_r)_j = a_j r^j$ . By choosing different  $r$ , one can obtain better precision  
87 for small  $j$  by choosing  $r < 1$  or large  $j$  by choosing  $r > 1$ .

88 **SM4. Computing maximum sum combination.** Given two sets  $A$  and  $B$  of the same  
89 size  $n$ . It is known that the maximum  $n$  sum combination of  $A$  and  $B$  can be computed in time  
90  $O(n \log(n))$ . The standard approach to solve the sum combination problem requires storing  
91 the variables in a heap — a highly dynamic binary tree structure that can be much slower  
92 to manipulate than arrays. In the following, we show an algorithm with roughly the same  
93 complexity but does not need a heap. This algorithm first sorts both  $A$  and  $B$  and then uses  
94 the bisection to find the  $n$ -th largest value in the sum combination. The key point is we can  
95 count the number of entries greater than a specific value in the sum combination of  $A$  and  $B$   
96 in linear time. As long as the data range is not exponentially large, the bisection can be done  
97 in  $O(\log(n))$  steps, giving the time complexity  $O(n \log(n))$ . We summarize the algorithm as  
98 in [Algorithm SM4.1](#).

---

**Algorithm SM4.1** Fast sum combination without using heap

---

```

Let  $A$  and  $B$  be two sets of size  $n$ 
// sort  $A$  and  $B$  in ascending order
 $A \leftarrow \text{sort}(A)$ 
 $B \leftarrow \text{sort}(B)$ 
// use bisection to find the  $n$ -th largest value in sum combination
high  $\leftarrow A_n + B_n$ 
low  $\leftarrow A_1 + B_n$ 
while true do
  mid  $\leftarrow (\text{high} + \text{low})/2$ 
   $c \leftarrow \text{count\_geq}(n, A, B, \text{mid})$ 
  if  $c > n$  then
    low  $\leftarrow \text{mid}$ 
  else if  $c = n$  then
    return collect_geq( $n, A, B, \text{mid}$ )
  else
    high  $\leftarrow \text{mid}$ 
  end
end
function count_geq( $n, A, B, v$ )
   $k \leftarrow 1$  ; // number of entries in  $A$  s.t.  $a + b \geq v$ 
   $a \leftarrow A_n$  ; // the smallest entry in  $A$  s.t.  $a + b \geq v$ 
   $c \leftarrow 0$  ; // the counting of sum combinations s.t.  $a + b \geq v$ 
  for  $q = n, n-1 \dots 1$  do
     $b \leftarrow B_{n-q+1}$ 
    while  $k < n$  and  $a + b \geq v$  do
       $k \leftarrow k + 1$ 
       $a \leftarrow A_{n-k+1}$ 
    end
    if  $a + b \geq v$  then
       $c \leftarrow c + k$ 
    else
       $c \leftarrow c + k - 1$ 
    end
  end
  return  $c$ 
end

```

---

In this algorithm, function `collect_geq` is similar the `count_geq` except the counting is replace by collecting the items to a set. Inside the function `count_geq`, variable  $k$  monotonously increase while  $q$  monotonously decrease in each iteration and the total number of iterations is upper bounded by  $2n$ . Here for simplicity, we do not handle the special element  $-\infty$  in  $A$  and  $B$  and the potential degeneracy in the sums. It is nevertheless important to handle them properly in a practical implementation.

**SM5. Technical guides.** This appendix covers some technical guides for efficiency, including an introduction to an open-source package `GenericTensorNetworks` [SM1] implementing the algorithms in this paper and the gist about how this package is implemented. One can install `GenericTensorNetworks` in a Julia REPL, by first typing ] to enter the `pkg>` mode and then typing

```
pkg> add GenericTensorNetworks
```

followed by an `<ENTER>` key. To use it for solving solution space properties, just go back to the normal mode (type `<BACKSPACE>`) and type

```
julia> using GenericTensorNetworks, Graphs
julia> # using CUDA
julia> solve(
    IndependentSet(
        Graphs.random_regular_graph(20, 3);
        optimizer = TreeSA(),
        weights = NoWeight(),
        openvertices = ()
    ),
    GraphPolynomial();
    usecuda=false
)
0-dimensional Array{Polynomial{BigInt, :x}, 0}:
Polynomial(1 + 20*x + 160*x^2 + 659*x^3 + 1500*x^4 + 1883*x^5 + 1223*x^6 + 347*x^7 + 25*x^8)
```

Here the main function `solve` takes three inputs: the problem instance of type `IndependentSet`, the property instance of type `GraphPolynomial` and an optional keyword argument `usecuda` to decide to use GPU or not. If one wants to use GPU to accelerate the computation, “using CUDA” must be uncommented. The problem instance takes four arguments to initialize: the only positional argument is the graph instance one wants to solve, the keyword argument `optimizer` is for specifying the tensor network optimization algorithm, the keyword argument `weights` is for specifying the weights of vertices as either a vector or `NoWeight()`, and the keyword argument `openvertices` is for specifying the degrees of freedom not summed over. Here, we use the `TreeSA` method as the tensor network optimizer, and leave `weights` and `openvertices` as default values. The `TreeSA` algorithm, which was invented in Ref. [SM7], performs the best in most of our applications. The first execution of this function will be a bit slow due to Julia’s just-in-time compilation. After that, the subsequent runs will be faster. The following diagram lists possible combinations of input arguments, where functions in the `Graph` are mainly defined in the package `Graphs`, and the rest can be found in `GenericTensorNetworks`.
